Antiepiligrin Cicatricial Pemphigoid

An Underdiagnosed Entity Within the Spectrum of Scarring Autoimmune Subepidermal Bullous Diseases?

Martin Leverkus, MD; Enno Schmidt, MD; Zelmira Lazarova, MD; Eva-Bettina Bröcker, MD; Kim B. Yancey, MD; Detlef Zillikens, MD

Background: Antiepiligrin cicatricial pemphigoid (AECP) is a chronic autoimmune subepidermal blistering disease characterized by autoantibodies to laminin 5 and clinical features of cicatricial pemphigoid. Only a few patients with AECP have been described to date. The aim of the present study was to analyze the relative frequency of AECP among patients with the clinical phenotype of cicatricial pemphigoid.

Observations: Serum from 16 consecutive patients with the clinical phenotype of cicatricial pemphigoid were included in this study. Nine patients had circulating IgG autoantibodies by indirect immunofluorescence on sodium chloride-split skin; patients' IgG bound to the epidermal side (n = 2), dermal side (n = 5), or both sides (n = 2) of this test substrate. Interestingly, all 5 cases with dermal binding immunoprecipitated laminin 5 from extracts and media of cultured keratinocytes, and 4 of these serum samples reacted with the α3 subunit of laminin 5 by immunoblotting. None of the patients with dermal binding of IgG demonstrated autoantibodies to type VII collagen.

Conclusion: Our data suggest that, among patients with the clinical phenotype of cicatricial pemphigoid, AECP may be more frequent than previously assumed.

Arch Dermatol. 1999;135:1091-1098

Cicatricial pemphigoid (CP) is a chronic, subepidermal autoimmune blistering disease of mucous membranes and skin. It may involve oral, ocular, nasal, pharyngeal, laryngeal, esophageal, and anogenital mucous membranes. Skin lesions appear in about 30% of patients with CP.1,4 Cicatricial pemphigoid is a heterogeneous disease with respect to the isotype of the associated autoantibodies in these patients (ie, IgG, IgA, or both), the side of skin split by 1-mol/L sodium chloride (NaCl) that is bound by their circulating autoantibodies, and the specific antigens targeted by their autoimmune response.

To date, the best characterized IgG autoantibodies in patients with CP and skin involvement (ie, patients whose disease is not limited to the eyes) are directed to BP180 (also referred to as type XVII collagen or BPAG2), laminin 5, or type VII collagen.5,6 In 1992, Domloge-Hultsch et al7 described a group of patients with CP who had IgG autoantibodies against a set of disulfide-linked polypeptides referred to as epiligrin. This protein, also designated nicein, kalinin, and BM 600 at that time, is now known to be identical to laminin 5, which is a heterotrimer consisting of α3β3γ2 subunits.

The aim of the present study was to analyze the relative frequency of antiepiligrin cicatricial pemphigoid (AECP) among patients with the clinical phenotype of CP in a regional referral center. The patients' skin and/or mucosa were analyzed by direct immunofluorescence (IF) microscopy. In addition, serum samples were studied by indirect IF for the presence of circulating IgG autoantibodies against BP180, the β4 subunit of α6β4 integrin, laminin 5, or type VII collagen. Of 16 consecutive patients with CP identified, 9 had IgG anti–basement membrane autoantibodies. We report the clinical features of these patients as well as their response to treatment. Our data suggest that, among patients with the clinical phenotype of CP, AECP represents an important subset.

RESULTS

IMMUNOFLUORESCENCE

All 16 patients included in this study had linear deposits of immunoreactants at the
PATIENTS AND METHODS

PATIENTS

Between June 1, 1989, and May 31, 1998, we analyzed the serum of 16 consecutive patients with the clinical phenotype of CP (all with a frankly scarring phenotype) at the immunofluorescence laboratory of the Department of Dermatology, University of Würzburg, Würzburg, Germany. Thirteen patients were treated at our department; the serum of 3 patients was sent to us from other institutions. Thirteen patients were women and 3 were men; their mean age was 65.3 years (range, 47-76 years). All patients showed different degrees of scarring involvement of oral (n = 15), ocular (n = 9), nasal (n = 5), pharyngeal (n = 6), laryngeal (n = 6), esophageal (n = 1), or anogenital (n = 7) mucous membranes as well as the skin (n = 8).

IF MICROSCOPY STUDIES

Perilesional skin or mucosa was studied by direct IF for deposits of IgG, IgA, IgM, and C3. For indirect IF, serum samples of patients and normal volunteers were reacted with 1-mol/L NaCl-split human skin as described previously.8 Slides for IF microscopy were examined independently by 2 investigators (including D.Z.).

IMMUNOPRECIPITATION STUDIES

Subconfluent monolayers of normal human keratinocytes were biosynthetically radiolabeled with methionine labeled with sulfur 35 (1.85 MBq/mL; specific activity, about 40.7 MBq/mmol; New England Nuclear, Boston, Mass) in methionine-free medium for 2 hours (for studies of cell extract) or overnight (for studies of conditioned medium). Samples were collected, processed, and studied by immunoprecipitation (IP) by means of serum from patients and normal controls as described previously.13-15 Immunoprecipitation samples were studied by Tris-glycine polyacrylamide gel electrophoresis and fluorography.

ANTIGEN EXTRACTION IMMUNOBLOT AND ENZYME-LINKED IMMUNOSORBENT ASSAY STUDIES

Dermal and epidermal extracts were prepared and analyzed as described.8 BP180 NC16A and fusion protein 4575 representing a C-terminal portion of the BP180 ectodomain11 were expressed as glutathione S-transferase (GST) fusion proteins and affinity purified by means of glutathione agarose.12 Immunoblot analysis and enzyme-linked immunosorbent assay studies with recombinant BP180 NC16A were performed as described previously.15 Laminin 5 was isolated from the extracellular matrix of cultured human keratinocytes, reduced, and studied by immunoblotting with serum from patients and reference controls.8,15 Alkaline phosphatase–conjugated goat F(ab’), anti–human IgG was used as a secondary antibody (dilution of 1:1000). Immunoblots were developed with an alkaline phosphatase–conjugate substrate kit (Bio-Rad, Hercules, Calif).

basement membrane zone (BMZ) in biopsy specimens from perilesional skin and/or mucosa. In 14 of 16 patients, deposits of IgG were found; in 12 patients, deposits of C3; and in 2 patients, deposits of IgA. Indirect IF microscopy studies of NaCl-split skin identified IgG anti-BMZ autoantibodies in 9 of these patients; titers ranged from 10 to 320. In contrast, none had circulating IgA anti-BMZ autoantibodies. In 2 cases, an epidermal staining pattern was observed; in another 2, a combined dermoepidermal staining pattern; and in 5 cases, a dermal staining pattern.

IMMUNOPRECIPITATION

In studies of conditioned medium from biosynthetically radiolabeled human keratinocytes, all 5 patients with IgG directed against the dermal side of NaCl-split skin (as well as a reference control patient with AECP) immunoprecipitated a series of disulfide-linked polypeptides that correspond to laminins 5 and 6, as previously described (see “Patients and Methods” section). The relative stoichiometry of polypeptides identified by patients 1 to 4 (lanes 3-6) as well as the reference positive control (lane 2) was approximately the same; the reactivity of autoantibodies from patient 5 (lane 7) dominated against laminin 5. Serum from a normal volunteer (negative control, lane 1) showed no specific reactivity to these proteins. The markers at the left margin indicate molecular weight (×103).

Figure 1. Reactivity of autoantibodies against proteins in biosynthetically radiolabeled human keratinocyte culture media. Serum from our 5 patients with antiepiligrin cicatricial pemphigoid (lanes 3-7) as well as a reference positive control serum with antiepipligrin cicatricial pemphigoid (lane 2) immunoprecipitated a series of polypeptides in keratinocyte media that correspond to laminins 5 and 6, as previously described (see “Patients and Methods” section). The relative stoichiometry of polypeptides identified by patients 1 to 4 (lanes 3-6) as well as the reference positive control (lane 2) was approximately the same; the reactivity of autoantibodies from patient 5 (lane 7) dominated against laminin 5. Serum from a normal volunteer (negative control, lane 1) showed no specific reactivity to these proteins. The markers at the left margin indicate molecular weight (×103).
By immunoblotting of epidermal extracts, 3 of the 14 patients with epidermal basement membrane deposits of IgG or C3 had autoantibodies to BP230, and 1 patient demonstrated antibodies to BP180. None of the 14 patients had autoantibodies to type VII collagen by immunoblot analysis of dermal extracts. With the use of recombinant forms of BP180, 2 of the 14 serum samples reacted with BP180 NC16A by both immunoblot analysis and enzyme-linked immunosorbent assay, and 3 serum samples immunoblotted a GST fusion protein containing a 49-amino acid stretch of the C-terminal region of BP180. Representative results of these analyses are shown in Figure 4. Three of the 14 serum samples were negative by indirect IF yet positive for reactivity with epidermal and recombinant proteins.

CLINICAL AND IMMUNOPATHOLOGIC FEATURES AND COURSE OF DISEASE OF THE 5 PATIENTS WITH AECP

Clinical characteristics of the 5 patients with AECP are summarized in Table 1, and examples are shown in Figure 5. Immunopathologic features of these patients are demonstrated in Table 2, and representative examples of direct and indirect IF are depicted in Figure 6 and Figure 7. The response to treatment in the 5 patients with AECP is briefly summarized below.

Patient 1 underwent intravenous pulse therapy, including dexamethasone (100 mg/d on 3 consecutive days) and cyclophosphamide (500 mg on day 1), for 10 cycles as described previously. Adenocarcinoma of the colon was detected after the sixth pulse, and the patient un-
In patient 3, treatment with dexamethasone and cyclophosphamide pulses was initiated and supplemented with 125 mg of cyclophosphamide orally daily between cycles, therapy that resulted in a good clinical response and stable disease. After 9 cycles of dexamethasone and cyclophosphamide treatment, the patient developed multiple enlarged lymph nodes that were found to signify metastases from a carcinoma of the cervix uteri for which hysterectomy had been performed 6 years earlier. The patient died of metastatic disease 1 year after diagnosis of AECP.

Patient 4 experienced clinical improvement with dexamethasone and cyclophosphamide pulse therapy. The patient died of pneumonia 6 weeks after the initiation of treatment.

Patient 5 showed no substantial improvement after different treatment regimens, including dapsone, colchicine, systemic glucocorticosteroids, high-dose intravenous immunoglobulins, and cyclosporine. The patient died of a perforated duodenal ulcer 2½ years after initiation of treatment.

Antiepiligrin cicatricial pemphigoid is a recently defined chronic subepidermal autoimmune vesiculobullous disease that primarily affects mucous membranes. It was previously considered to comprise a small subgroup of patients with CP. Direct IF examination of perilesional mucous membranes or skin biopsy specimens from patients with AECP demonstrates linear deposits of IgG and C3 at the BMZ. Indirect IF studies show binding of the IgG autoantibodies to the dermal side of NaCl-split human skin. By IP of radiolabeled condi-
tioned keratinocyte medium or by immunoblot analysis of extracellular matrix of cultured human keratinocytes, the autoantibodies were found to recognize laminin 5. Laminin 5 is an anchoring filament–lamina densa associated heterotrimer (α3β3γ2). More recently, it was found that most patients’ autoantibodies bind to the α3 subunit of this protein.14,16 Some patients have antibodies to laminin β3, and some show reactivity to both the

α3 and γ2 subunits. The pathogenic relevance of autoantibodies to laminin 5 has been demonstrated in an animal model. When rabbit anti–laminin 5 antibodies were passively transferred into neonatal mice, the animals developed subepidermal bullous disease that duplicated the findings seen in patients with AECP.

In this study, we characterized the immune response in 16 consecutive patients with clinical and immunopathologic features of CP that were identified at the Department of Dermatology at the University of Würzburg during a period of 9 years. All patients had linear deposits of IgG and C3 at the BMZ of perilesional skin biopsy specimens.

*CP indicates cicatricial pemphigoid; BMZ, basement membrane zone; IF, immunofluorescence; HK, human keratinocyte; IP, immunoprecipitation; ECM, extracellular matrix; IB, immunoblot; minus sign, absent; plus sign, present; and ND, not done. All patients had linear deposits of IgG and C3 at the BMZ of perilesional skin biopsy specimens.
†Indirect immunofluorescence microscopy on 1-mol/L sodium chloride–split human skin; results in parentheses correspond to titers of anti-BMZ IgG.
‡Because HK medium has been shown to be a source of immunoreactive laminin 5 (L5) and laminin 6 (L6), the results are presented accordingly. The IgG autoantibody reactivity in patient 5 remained against L5.
§Laminin 5 is the dominant isoform identified in biosynthetically radiolabeled keratinocyte extracts; hence, all results are noted accordingly.
¶BP180 457S represents a C-terminal stretch of BP180 consisting of 49 amino acids.

patients with CP. However, our study selected patients on the basis of the clinical finding of a scarring phenotype, whereas Chan et al selected their patients on the basis of the finding of involvement of mucous membranes (ie, a scarring phenotype was not a requirement for inclusion in their study).

Summary data regarding clinical and immunopathologic features of 14 cases of AEC have been reported to date. The clinical features of these patients have been indistinguishable from those of patients with other forms of CP.20,26-33 All of our patients with AEC had involvement of the oral mucosa, and in all but 1 patient the oropharynx and larynx were also affected. Interestingly, all of our patients were women. This is in contrast to the previous cases, in which 8 of 13 patients were male. Our observation may be an incidental finding or may represent regional or racial differences within our population of northwestern Bavaria. Two of our 5 patients with AEC suffered from an associated malignant tumor. In 1 patient, metastatic disease from a cervical adenocarcinoma was detected shortly after AEC was diagnosed. In a second patient, disease activity was markedly reduced when an adenocarcinoma of the colon was removed. After surgery, no new blisters occurred, and this patient has currently tapered off treatment. Five other cases of AEC have been reported in association with cancer.27,28-31,34 Whether these findings indicate a causal relation between AEC and malignant neoplasms or rather represent a coincidence requires further study of a larger group of patients during a longer period. The survival rate of our patients with AEC was not favorable. Two patients with AEC died of complications of immunosuppressive treatment. Another patient died of metastatic carcinoma of the cervix 1 year after the diagnosis of AEC. The characterization of different subgroups among patients with different subtypes of CP may identify individuals at risk for severe disease, certain spectrums of involvement, or specific associations. Moreover, such distinctions may eventually lead to the development of more effective and specific treatment regimens as advances in immunotherapy are forthcoming.

We add 5 new cases of AEC to the literature concerning this recently identified entity. Five of 9 patients with clinical features of CP and detectable levels of circulating IgG anti-BMZ autoantibodies suffered from this disease. Our findings suggest that, among patients with the clinical phenotype of CP, AEC may represent an important subset.
