Photodistribution of Blue-Gray Hyperpigmentation After Amiodarone Treatment

Molecular Characterization of Amiodarone in the Skin

Background: For decades, the photodistributed blue-gray skin hyperpigmentation observed after amiodarone therapy was presumably attributed to dermal lipofuscinosis. Using electron microscopy and high-performance liquid chromatography, we identified amiodarone deposits in the hyperpigmented skin sample from a patient treated with this antiarrhythmic agent. Our findings therefore indicate that the hypothesis relating the blue-gray hyperpigmentation to lipofuscin should be challenged.

Observations: A 64-year-old man, skin phototype III, presented with asymptomatic skin hyperpigmentation that had been slowly developing on sun-exposed areas since April 2004. He had been taking amiodarone for 4 years (cumulative dose, 277 g). Electron microscopy did not show lipofuscin pigments in his skin. Conversely, abundant electron-dense membrane-bound granule deposits were observed in most of the dermal cells (fibroblasts, macrophages, pericytes, Schwann cells, and endothelial cells), especially in photoexposed skin. High-performance liquid chromatography confirmed that the skin deposits were composed of amiodarone. These results demonstrate that amiodarone hyperpigmentation is related to drug deposition on photoexposed skin.

Conclusion: Amiodarone-related hyperpigmentation should be considered a skin storage disease that is secondary to drug deposition.

Arch Dermatol. 2008;144(1):92-96

REPORT OF A CASE

A 64-year-old man, skin phototype III, presented with progressive, asymptomatic skin hyperpigmentation that had been slowly developing on sun-exposed areas since April 2004. His medical history was remarkable for myocardial infarction, ventricular arrhythmia, and heart failure. He had no known history of drug allergy. For several years, he had been treated with acebutolol (200 mg/d), lisinopril (10 mg/d), simvastatin (20 mg/d), and lysine acetylsalicylate (75 mg/d). He had also taken amiodarone (Cordarone) at a dosage of two 200-mg tablets per day, 5 days per week, from 2001 until July 2005. The cumulative dose was estimated to be 277 g over 4½ years. His physical examination revealed photodistributed, blue-gray hyper-
pigmentation of the face and ears, sparing the area under the nose, all eyelids, nasolabial folds, wrinkles, and submental and postauricular areas (Figure 1). Phototests revealed a polychromatic minimal erythema dose at 600 mJ/cm² (reference value, ≥400 mJ/cm²). The results of the UV-A phototest (13 J/cm²) were negative after 24 hours, with mild hyperpigmentation. Histologic examination of a pigmented skin specimen revealed numerous macrophages accumulated around superficial dermal vessels. The cytoplasm of these cells showed brownish deposits that were positive on periodic acid–Schiff and Fontana stains (Figures 2, 3, and 4).

Electron microscopy of a nonpigmented skin sample showed the presence of a few homogeneous strongly electron-dense granules confined to the upper dermis, whereas a pigmented skin sample revealed numerous similar granules within the thickness of the dermis. These deposits were localized mainly in fibroblasts as well as in other cells, particularly macrophages, endothelial cells, and Schwann cells (Figure 5). At high magnification, they appeared to be surrounded by a membrane. There were no abnormal deposits within the epidermis, hair follicles, or sebaceous glands. No lipofuscin deposits were observed in the pigmented skin sample from our patient.

**TECHNIQUE**

The first step of the molecular identification of amiodarone deposits in the skin involved the extraction of amiodarone from a skin biopsy specimen. A skin biopsy (punch, 4 mm; 8 mg) was performed on the pigmented skin of the face to demonstrate the presence of drug deposits by extracting the active molecule of amiodarone. Accordingly, the skin specimen was homogenized with 10 mL of methanol and kept at 5°C for 24 hours. The homogenate was then crushed and filtered. The filtrate was evaporated to dry-
null
process.\textsuperscript{12} In a previous report, the presence of high concentrations of iodine, which was observed on electron probe analysis, suggested that the cutaneous deposits are made up of amiodarone itself or a metabolite.\textsuperscript{5} Our results confirm this hypothesis. After the extraction procedure that was performed on the hyperpigmented skin of our patient’s face, HPLC of the skin sample showed 4 peaks corresponding to 4 retention times: 0.707 minutes, 0.868 minutes, 1.447 minutes, and 8.207 minutes. Later on, after each sequential addition of commercial amiodarone (extracted from Cordarone tablets), HPLC revealed a clear increase of the peak at 8.207 minutes. This finding suggests that the molecule corresponding to the retention time of 8.207 minutes and the commercial amiodarone that was added are the same compound. To be more precise, the UV absorption spectrum of each peak was determined at 8.207-minutes. These UV absorption spectra were perfectly identical (Figure 6). Therefore, in this case, the molecule extracted from the skin, which showed a peak at 8.207 minutes, is amiodarone. We were not able to identify the nature of the other 3 molecules corresponding to 0.707, 0.868, and 1.447 minutes. These molecules may represent amiodarone photoproducts/metabolites, skin components such as melanin, or cutaneous deposition of other drugs taken by the patient. The recognition of these molecules is not easy because amiodarone metabolism is more complex than has generally been accepted. It was observed that mono-N-desethylamiodarone may further be cleared by hydroxylation, dealkylation to di-N-desethylamiodarone, and deamination to deaminated amiodarone.\textsuperscript{13} In our case, HPLC analysis could neither exclude nor confirm the presence of lipofuscin. However, electron microscopy showed that lipofuscin pigment was absent in our patient’s skin. This finding indicates that the hypothesis relating the blue-gray hyperpigmentation to lipofuscin should be challenged. Also, direct evidence of massive amiodarone deposits in the hyperpigmented skin on electron microscopy provides a strong argument in favor of a direct pathogenic role for amiodarone. There are numerous reasons to question the role of lipofuscin as a causative factor in amiodarone hyperpigmentation. Lipofuscin is a naturally occurring autofluorescent lipopigment that accumulates in aging cells as a normal part of senescence; it is called the wear-and-tear or aging pigment. Because this material exhibits fluorescence, lipofuscin has been described by its spectral properties, with an excitation between 320 and 480 nm and an emission wavelength between 460 and 630 nm, with a peak at 580 nm corresponding to yellow and not blue fluorescence.\textsuperscript{14,15} Conversely, electron microscopic examination of the sun-exposed skin of patients without amiodarone discoloration shows pigment deposits similar to those already described in patients with amiodarone hyperpigmentation in exposed and nonexposed skin.\textsuperscript{7} Finally, the presence of amiodarone deposits in the skin, with or without lipofuscin, is able to induce the blue-gray hyperpigmentation. This pigmentation could be explained by the Tyndall effect, in which dermal pigment, whether melanin, iron, or other pigment, is perceived as blue, gray, or blue-gray.

In conclusion, our results confirm that amiodarone blue-gray hyperpigmentation should be considered a skin storage disease that is secondary to drug deposition. A
comparative study with nonpigmented, photoprotected skin would need to be carried out to find out whether the other 3 unidentified molecules (0.707 minutes, 0.868 minutes, and 1.447 minutes) on HPLC are photoproducts of amiodarone.
